About the Data Management Program

The Texas Data Management Program is a statewide network of information resources. Its primary purpose is to make census materials and data available to various users interested in demographic information and trends. The Data Management Program network is coordinated and administered by the Texas Advisory Commission on Intergovernmental Relations.

NET MIGRATION IN TEXAS: 1970 - 1980
BY AGE AND SEX
FOR WHITES AND NONWHITES

INTRODUCTION

The State of Texas experienced an unprecedented rate of inmigration from 1970 to 1980. Over 1.4 million more persons migrated to the State than left for other states during the 1970s. This accounted for 45 percent of the State's total growth of 3.1 million persons from 1970 to 1980 (55 percent was the result of natural increase) and far exceeded the amount of the State's growth that has resulted from net migration in other decades of this century.

The levels and rates of net migration vary widely, however, from one area to another in the State and among different age groups, races, or by sex. In order to understand the effects of migration within subparts of the State or for specific population segments, it is essential to have information on those levels and rates for each area and population segment. Data on the rates of migration for subpopulations and for units such as counties are essential elements for completing cohort-component estimates and projections for small areas. Estimates of age-, sex-, and race-specific rates of migration are essential for long-term planning as well as for basic analysis of migration patterns.

Recognizing the importance of such estimates, the Department of Rural Sociology in the Texas Agricultural Experiment Station at Texas A&M, under the sponsorship of the Texas Data Management Program, developed the estimates of age-, sex-, and race specific migration and migration rates for the 1970-1980 decade presented in this volume. The total number of migrants and migration rates for males and females, the numbers and rates for each of 16 five-year age groups and for the total population, and the numbers and rates for whites and nonwhites are shown for the State as a whole and for each of the State's 254 counties. No attempt is made in this report to interpret these estimates; rather, the intent is to provide a reference source for use by persons throughout the State.

The report contains two sections. The first section describes the methodology used in computing the net migration estimates; the second section presents data tables showing the net migration estimates and rates for the State and each of its 254 counties. Additional information on these estimates can be obtained by contacting the authors at:

GENERAL CONSIDERATIONS IN COMPUTING NET MIGRATION ESTIMATES

Because of the lack of direct data on migration, nearly all estimates of net migration are computed by using residual estimation methodologies. That is, migration for a given period of time is assumed to be the difference (the residual) between total population change in an area and that part of the change that is accounted for by natural increase (births minus deaths). These techniques provide estimates of net migration for a given period by subtracting natural increase from total population change.

Thus:

$$NM_{t_1,t_2} = P_{t_2} - P_{t_1} + D_{t_1,t_2} - B_{t_1,t_2}$$

or

$$NM_{t_1,t_2} = P_{t_2} - EP_{t_2}$$

where: NM_{t_1,t_2} = net migration between time 1 (t_1) and time 2 (t_2)

EP_{t_2} = $P_{t_1} + B_{t_1,t_2} - D_{t_1,t_2}$ (= expected population at time 2)

P_{t_1} = census population count at time 1

P_{t_2} = census population count at time 2

D_{t_1,t_2} = deaths between time 1 and time 2

B_{t_1,t_2} = births between time 1 and time 2 (this component is applicable only to the first cohort)

By using this formula and making its elements specific to a given age, sex, and racial/ethnic group (i.e., cohort) for a specified area, it is possible to compute net migration estimates for cohorts in an area.

The accuracy of net migration estimates computed using residual methods is limited by the accuracy of available data on population change and on the rates of change in natural increase as well as by the form of survival rates employed in the computations. Since the data usually employed in computing such estimates are taken from census counts and from state vital statistics registration systems, the accuracy can be seen as a function of the accuracy of the census population counts and the completeness of registration of births and deaths. In addition, because estimates of the

expected population are usually derived by the use of survival rates, the form and type of survival rates used also affect the estimates obtained. Finally, if estimates for subgroups or cohorts of the population (e.g., estimates for males and females, whites and nonwhites, cities, counties, etc.) are to be computed, the accuracy of net migration estimates will be affected by the ability to accurately attribute population and vital events to the cohorts and geographic areas of interest.

In sum, in computing net migration estimates, it is necessary to take into account the potential differences between census counts and actual population values (often referred to as the error of closure or the undercount and/or overcount rate), the completeness of coverage of the vital registration system, and the consistency of the techniques used to estimate surviving populations from one period to another and for attributing population events to cohorts of the population in specific areas.

Nearly all recently produced estimates of county-level age-, sex-, and race-specific migration (Bowles and Tarver, 1965; Bowles et al., 1975) assume completeness of coverage in vital events registration and in attribution to subgroups. However, three techniques which vary in the means used to survive populations from one time period to another and to account for errors of closure are commonly used in making estimates of net migration. Because each of these techniques is widely used in computing net migration, each is briefly described and the advantages and disadvantages are discussed. This is followed by a description of the specific methods used in computing the rates presented in this volume.

ALTERNATIVE METHODS FOR ESTIMATING NET MIGRATION

The three most widely used techniques for estimating net migration are: (1) the life table survival-rate method, (2) the vital-statistics method, and (3) the census survival-ratio method. Each of these has certain advantages and disadvantages.

Life Table Survival-Rate Method

The life table survival-rate method uses survival rates derived from life tables. Life tables are

readily available for most states and life table survival rates are easily derived from such tables (see Shryock and Siegel, 1980; Murdock, 1982). This method is the easiest to use. It involves the simple application of the survival rates for a base period to the population in a cohort at the base period (t_1) to obtain the expected population at the second period of time (t_2). The difference between the expected population and the census count (or the expected population and the total number of births for the first cohort) is assumed to be net migration.

The advantages of using this approach lie in the ease with which survival rates can be obtained. The disadvantages of this method result from the assumption that the survival rates for the base period adequately characterize mortality trends throughout the estimation period. When rates of mortality are declining rapidly (as was the case in the 1970s), such an assumption will result in an overestimate of the number of deaths during the estimation period and an equivalent underestimation of migration. Although this problem can be partially eliminated by using an average of life table survival rates for the base and end points of the estimation period (Shryock and Siegel, 1980), such rates are often not available for end points and even when they are, such averages often do not provide an accurate picture of the average mortality experience of a cohort over the estimation period. In addition, the use of this procedure does not address the problem of closure. One must still decide whether or not and how to adjust base and end point census counts for undercount or overcount. Finally, if the average of survival rates for a beginning and an end period is used, the survival rates computed using this technique will be affected by vital events occurring to persons who migrated into or out of the area during the estimation period. Data are not available to adjust life table survival rates to take these events into account.

Vital-Statistics Method

The vital-statistics method has been seen by some (Siegel and Hamilton, 1952) as the most exact method for estimating net migration. It is exact because, unlike the other two "survival rate"

methods, which indirectly estimate the number of deaths in a cohort by using survival rates, the vital-statistics method uses direct data on the number of deaths in a cohort in its computations.

The advantage of this method, then, lies in its "theoretical" exactness. Its disadvantages result from the fact that to obtain such exactness one must be able to separate deaths and births attributable to persons migrating into and out of the area during the estimation period from those for persons who did not migrate during the estimation period. In addition, one must obtain very detailed data on the date of birth or death to properly attribute events to cohorts. It is often impossible to obtain such data. Finally, this method does not provide a means of adjusting census counts for errors of closure.

Census Survival-Ratio Method

The census survival-ratio method uses the same computational structure as the life table survival-rate method but the survival rates employed are computed differently. In the census survival-ratio method, survival rates are computed by dividing the population in a cohort at the end of the estimation period by the population in the same cohort ten years earlier. Thus, the ten-year survival rate for persons 20-29 in 1980 would be obtained by dividing the number of persons 20-29 in 1980 by the number 10-19 in 1970. These ratios are computed at the national level (because data on international migration are available at the national level and adjustments for the total number of such migrants can be made) and are assumed to apply to the population in the area of interest.

The advantages of this method include the fact that, when derived from data for the nation, the need to remove the effects of events occurring to immigrants (as is necessary in the other methods) is eliminated. Also, the method provides survival rates that are adjusted for errors of closure between the two censuses (Hamilton and Henderson, 1944; US Bureau of the Census, 1965). In addition, this method was selected for use in previous net migration computations for counties (Bowles and Tarver, 1965; Bowles et al., 1975), and thus its use allows direct comparisons to be made between

its rates and those for earlier periods. Its disadvantages lie in the fact that the survival rates calculated for the nation must be assumed to apply at the state and local level.

Each of the three methods described above has certain advantages and disadvantages. Which should be used at a given time and place depends upon the characteristics of the data available for the area of interest.

METHODS USED TO COMPUTE NET MIGRATION ESTIMATES FOR TEXAS COUNTIES, 1970-1980

In the rates reported in this volume, it was necessary to address several concerns and questions related to the data available for Texas for 1970 and 1980. These questions included:

(1) Should 1970 or 1980 or both census counts be adjusted for potential errors of closure (undercounts or overcounts)?

(2) Should vital statistics be used and if so, should they be adjusted for potential problems in coverage?

(3) Given the change in the means by which racial/ethnic groups were identified between the 1970 and the 1980 censuses, should census counts be adjusted to take such changes into account?

(4) Given the small population size of many Texas counties, should rates computed for such areas be adjusted to control for the chance fluctuations that occur when such rates are computed?

(5) Should adjustments be made for unique events of the 1970s that may have affected the migration rates in the State?

These issues were addressed as described on the following pages.

Because the census survival-ratio method provides a means to overcome potential problems in adjusting for errors of closure, requires no direct use of vital statistics data, and has been employed in previous attempts to compute county-level net migration estimates (Bowles and Tarver, 1965; Bowles et al., 1975), it was selected for use in computing the rates reported in this volume. These ratios were computed for each age, sex, and race group from data provided by the US Bureau of the Census with adjustments being made for both armed forces overseas and international immigration between 1970 and 1980. These ratios were then assumed to apply to all counties in Texas for the 1970-1980 period. The use of the census survival-ratio method allowed us to address each of the first two concerns.

The need to adjust for changes in the definition of racial/ethnic groups between 1970 and 1980 was apparent. Two problems were evident in regard to this dimension. First, Spanish-Origin was determined by the use of Spanish surname in 1970 but was based on self-identification in 1980. The effects of these two different means of identifying Spanish-Origin are unknown. Second, because race and ethnicity were discerned by the use of two separate questions in 1980, there are significant problems in uniquely identifying Anglos in 1980. This is a result of the fact that many Spanish-Origin persons identified their race as "other" rather than as white in the 1980 census, unlike the pattern in 1970 when most Spanish-surnamed persons were classified as white. Thus, it was impossible to identify a comparable population of Anglos in 1970 and 1980, and separate rates for Anglo, Spanish-Origin, and Black populations could not be computed. However, because of the existence of a specialized data set compiled by the Census Bureau for the Federal Office of Management and Budget (OMB) that provided population figures by age and sex for whites and nonwhites for 1980 that are comparable to those for 1970, it was possible to compute rates for white and nonwhite groups. Net migration estimates for whites and nonwhites are thus presented in this report.

Because the value of rates when based on small population values can fluctuate widely, we also evaluated the possibility of using various forms of rate adjustment to eliminate such fluctuations. We

evaluated several smoothing and standardization procedures (Shryock and Siegel, 1980), but concluded that any alterations in rates from those obtained by the standard form of computation would not be useful for most of the purposes for which such rates will be used. Users of these data should be aware of the limitations introduced by the computation of rates for small-population areas, however, and be careful in the use of these rates for such areas.

Finally, we also examined the possibility of adjusting the rates to take into account certain events of the 1970s that might have affected net migration patterns. In particular, we attempted to evaluate the effects of the Vietnam demobilization on migration rates. Although the total census populations for 1970 and 1980 for the nation used in computing the census survival ratios were adjusted for differences in the number of persons in the armed forces who were overseas in 1970 and 1980, no data were available to make such adjustments at the county level. Thus, although Texas' proportion of the armed forces population is larger than its proportion of the US population, and its migration rates may have been affected by the fact that some returning armed forces personnel may have been incorrectly counted as migrants, the effects of this event on the net migration rates appear to be quite small and simply cannot be determined (due to the lack of the necessary data) at the county level. Adjustments for this and similar unique events were thus impossible.

In sum, the procedures employed represent our best attempt to address numerous potential limitations in the data available for estimating net migration for Texas counties for the 1970 to 1980 decade. Although the procedures used require that numerous assumptions be made, the estimates presented reflect the most current methodological procedures for migration estimation.

Four steps were used in computing the rates presented in this volume. Although the computations were performed for each age, sex, and race group on an element-by-element basis, we describe the steps using a simplified matrix approach. This heuristic device provides an easier to understand description of the relatively complex process involved in computing such rates.

Step 1: Deriving Census Survival Ratios

National census survival ratios by age and sex for white and nonwhite groups were computed in the manner described previously, using the OMB consistent population values and the adjustments both for armed forces overseas and immigrants previously discussed. Ratios for 18 five-year age cohorts were computed for each sex and racial group (i.e., for whites and nonwhites). Data on births during the 1970s were used to obtain the values for the first two cohorts (i.e., those 0-4 and 5-9 years of age in 1980) in each sex and race group. The national survival ratios computed for each of the 18 cohorts were assumed to be applicable to all counties in Texas.

Step 2: Estimating Expected Population in 1980

Given census survival ratios, the expected population in each cohort can be estimated in a straightforward manner. Two matrices are required to estimate expected population by age for each sex and race group. One of these matrices is a beginning population matrix, B_{254x18}, formed by adding two age cohorts, 0-4 and 5-9 years of age, born between 1970 and 1980, to the existing five-year cohorts in 1970. As shown in the following matrix, the element $b_{1,1}$ represents the 0-4 years-old cohort born between 1976 and 1980 in county 1, and the element $b_{1,2}$ represents the 5-9 year-old cohort born between 1970 to 1975 in county 1. The data on births were obtained from the Texas Department of Health, and the data on existing cohorts for 1970 (e.g., $b_{i,3} \cdots b_{i,18}$) were taken from Bowles et al. (1975). Thus, in the B Matrix, each element $b_{i,j}$ represents the population for each five-year age group in each county (with the subscript i representing the county number and subscript j representing the five-year cohort).

B Matrix

$$\begin{bmatrix} b_{1,1} & b_{1,2} & \cdots & b_{1,17} & b_{1,18} \\ b_{2,1} & b_{2,2} & \cdots & b_{2,17} & b_{2,18} \\ \vdots & \vdots & & \vdots & \vdots \\ b_{253,1} & b_{253,2} & \cdots & b_{253,17} & b_{253,18} \\ b_{254,1} & b_{254,2} & \cdots & b_{254,17} & b_{254,18} \end{bmatrix}$$

The other required matrix is a diagonal matrix containing the census survival ratios by age for a

particular sex and race group, R, arranged as follows:

R Matrix

$$\begin{bmatrix} r_1 & 0 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ 0 & r_2 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & & & & & & \cdot & \cdot \\ \cdot & \cdot & & \cdot & & & & & \cdot & \cdot \\ \cdot & \cdot & & & \cdot & & & & \cdot & \cdot \\ \cdot & \cdot & & & & \cdot & & & \cdot & \cdot \\ \cdot & \cdot & & & & & \cdot & & 0 & \cdot \\ \cdot & \cdot & & & & & & \cdot & r_{17} & 0 \\ 0 & 0 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 0 & r_{18} \end{bmatrix}$$

(Each element r_j stands for the census survival ratio for a five-year age group.)

The expected population for each age group in each county for a particular sex and racial group can then be obtained by simply multiplying these two matrices. The result is a 254 x 18 matrix of expected populations, $X_{254,18}$, for that particular sex and race group. This matrix can be represented as follows:

X Matrix

$$\begin{bmatrix} x_{1,1} & x_{1,2} & \cdots & x_{1,17} & x_{1,18} \\ x_{2,1} & x_{2,2} & \cdots & x_{2,17} & x_{2,18} \\ \cdot & \cdot & & \cdot & \cdot \\ \cdot & \cdot & & \cdot & \cdot \\ \cdot & \cdot & & \cdot & \cdot \\ x_{253,1} & x_{253,2} & \cdots & x_{253,17} & x_{253,18} \\ x_{254,1} & x_{254,2} & \cdots & x_{254,17} & x_{254,18} \end{bmatrix}$$

Step 3: Estimating Net Migration

To obtain the net migration estimates by age, sex, and racial group for each county, expected population values for the end period (1980) must be compared to the actual census counts for the end period (1980). The end population matrix, E_{254x18} for the corresponding sex and racial group was again taken from the OMB file obtained by the US Bureau of the Census. This file was used to construct a matrix that is similar in structure to the B_{254x18} matrix described previously, but its elements are based on actual 1980 population counts. By taking the difference between the E_{254x18} and the X_{254x18} matrices, the residuals for each element can be

obtained. These elements (the residuals) form a new matrix which consists of the estimates of net migration for each age group in each county for a particular sex and race cohort. In matrix form, this computation can be expressed as follows:

$$X_{254x18} - E_{254x18} = M_{254x18}$$

$$\begin{bmatrix} x_{1,1} & x_{1,2} & \cdots & x_{1,18} \\ x_{2,1} & x_{2,2} & \cdots & x_{2,18} \\ & & & \\ x_{254,1} & & \cdots & x_{254,18} \end{bmatrix} - \begin{bmatrix} e_{1,1} & e_{1,2} & \cdots & e_{1,18} \\ e_{2,1} & e_{2,2} & \cdots & e_{2,18} \\ & & & \\ e_{254,1} & & \cdots & e_{254,18} \end{bmatrix} = \begin{bmatrix} m_{1,1} & m_{1,2} & \cdots & m_{1,18} \\ m_{2,1} & m_{2,2} & \cdots & m_{2,18} \\ & & & \\ m_{254,1} & & \cdots & m_{254,18} \end{bmatrix}$$

To obtain the net migration estimate for the age group 75 years and over, the estimates for three five-year age groups, 75-79 ($m_{i,16}$), 80-84 ($m_{i,17}$), and 85+ ($m_{i,18}$) were added together. Estimates for the total population (whites plus nonwhites) were obtained by simply summing the white and nonwhite components.

Step 4: Deriving Net Migration Rates

Given estimates of the number of net migrants, deriving net migration rates involves a simple element-by-element division of the net migration matrix (M_{254x18}) by the expected population matrix (X_{254x18}). For example, the net migration rate for persons 0-4 years of age in county 1 for a particular sex and racial population can be obtained by dividing $m_{1,1}$ by $x_{1,1}$; and the net migration rate for age group 70-74 in county 254 for the same sex and race group can be obtained by dividing $m_{254,15}$ by $x_{254,15}$. To obtain net migration rates for the 75+ age group, the $x_{i,16}$, $x_{i,17}$, and $x_{i,18}$ elements were added together to form the expected population for the age group 75 years of age and older and then used as the denominator for calculating the migration rate for the age group 75 years of age and older. All rates are per 100 persons. Rates for the total population were computed in a similar manner using values obtained by summing white and nonwhite elements.

The methods used to compute the net migration estimates presented here thus represent commonly used and widely accepted procedures. They were applied with careful consideration being given to potential data and methodological problems. However, potential users of these net migration estimates should use them with a clear recognition of their methodological bases and limitations.

NET MIGRATION ESTIMATES

The following 255 tables present estimates of net migration and of net migration rates for the State and for each of its 254 counties (arranged in alphabetical order). Each of these 255 tables is arranged in an identical manner with net migration estimates for each age, sex, and race cohort being presented in the top panel and the corresponding rates shown in the bottom panel. All rates are per 100 persons.
